Regression discontinuity is a popular tool for analyzing economic policies or treatment interventions. This research extends the classic static RD model to a dynamic framework, where observations are eligible for repeated RD events and, therefore, treatments. Such dynamics often complicate the identification and estimation of long-term average treatment effects. Empirical papers with such designs have so far ignored the dynamics or adopted restrictive identifying assumptions. This paper presents identification strategies under various sets of weaker identifying assumptions and proposes associated estimation and inference methods. The proposed methods are applied to revisit the seminal study of [Cellini, Fer](#page-25-0)[reira, and Rothstein](#page-25-0) [\(2010\)](#page-25-0) on long-term effects of California local school bonds.

KEYWORDS. Long-term treatment effects, dynamic regression discontinuity, semiparametric, varying coefficient logit.

JEL classification. C31.

1. Introduction

Regression discontinuity (RD) models, which can be traced back to [Thistlethwaite and](#page-28-0) [Campbell](#page-28-0) [\(1960\)](#page-28-0), are popular in policy evaluations or other settings of treatment effect analysis. The set-up exploits discontinuity in the design of many policies to nonparametrically identify treatment effects for observations near the eligibility cutoff. Classic

studies of RD identification, estimation, and inference include [Hahn, Todd, and van der](#page-27-0) [Klaauw](#page-27-0) [\(2001\)](#page-27-0), [Porter](#page-28-0) [\(2003\)](#page-28-0), [Lee](#page-27-0) [\(2008\)](#page-27-0), [Imbens and Lemieux](#page-27-0) [\(2008\)](#page-27-0), [Calonico, Catta](#page-25-0)[neo, and Titiunik](#page-25-0) [\(2014\)](#page-25-0), and Calonico, Cattaneo, Farrell, and Titiunik [\(2019\)](#page-25-0), among many others. [Cattaneo and Titiunik](#page-25-0) [\(2022\)](#page-25-0) provide a comprehensive literature review.

While the classic RD set-up, either sharp or fuzzy, is static in empirical applications we often see situations where each individual faces multiple rounds of RD and, therefore, could potentially receive repeated treatments. For example, voter-approved measures such as unionization (e.g., [DiNardo and Lee](#page-26-0) [\(2004\)](#page-26-0), [Lee and Mas](#page-27-0) [\(2012\)](#page-27-0)) or local school bonds (e.g., [Cellini, Ferreira, and Rothstein](#page-25-0) [\(2010\)](#page-25-0)) could be put in front of voters recurrently. A large body of literature in political science and economics (e.g., [Lee](#page-27-0) [\(2008\)](#page-27-0), [Pettersson-Lidbom](#page-28-0) [\(2008\)](#page-28-0), [Ferreira and Gyourko](#page-26-0) [\(2009\)](#page-26-0), [Colonnelli, Prem, and](#page-26-0) [Teso](#page-26-0) [\(2020\)](#page-26-0)) uses RD to study the effect of political races that happen on a regular basis. [Dube, Giuliano, and Leonard](#page-26-0) [\(2019\)](#page-26-0) and [Johnson](#page-27-0) [\(2020\)](#page-27-0) examine the peer effect of RD treatments. Their setting is repeated as well because the same individual can be exposed to different peer treatments at different points of time.

The repeated treatment design brings complications to identifying long-term effects in the RD setting just as in other non-RD settings. As [Heckman, Humphries, and Vera](#page-27-0)[mendi](#page-27-0) [\(2016\)](#page-27-0) discuss, in repeated/sequential treatment settings reduced-form analysis can only identify a mixed bag of effects, called the long-term *total* effect. For policy analysis, researchers often want to distinguish a long-term *direct* effect, or the "clean" long-term effect of an earlier treatment with no subsequent treatments [\(Heckman,](#page-27-0) [Humphries, and Veramendi](#page-27-0) [\(2016\)](#page-27-0)), from the mixed bag.

In the California education bond example studied by [Cellini, Ferreira, and Rothstein](#page-25-0) [\(2010\)](#page-25-0) (CFR), for example, policymakers are interested in identifying the long-run effect of passing a local education bond on education expenditure, test scores, and local house prices. For the purpose of identification, one wishes that the education bond voting would only take place once. Then, comparing long-run outcomes between school districts that barely pass and barely miss the vote share cutoff, would give average longterm direct effects of interests (for those school districts at the vote share cutoff). In reality, education bond measures can be put forward repeatedly. As is discussed in CFR, the difference in observed long-run outcomes at the RD cutoff only captures an average total effect that is also influenced by subsequent bond authorizations. For example, school districts failing to pass the initial bond measure are more likely to put forward another bond measure in later periods [\(Cellini, Ferreira, and Rothstein](#page-25-0) [\(2010\)](#page-25-0)).

Among the empirical literature on repeated RD settings, CFR and subsequent studies adopting their methods (e.g., [Darolia](#page-26-0) [\(2013\)](#page-26-0), [Abott, Kogan, Lavertu, and Peskowitz](#page-24-0) [\(2020\)](#page-24-0)) are the only ones, as far as the authors know, that seek proper identification of average long-term direct effects. Other empirical studies either ignore the repeated design or opt to only study immediate effects and/or long-term total effects. CFR proposes to identify average long-term direct effects from total effects with a recursive RD strategy and a more parametric event study strategy. Recently, [Gallen, Joensen, Johansen, and](#page-26-0) [Veramendi](#page-26-0) [\(2023\)](#page-26-0) extend CFR's recursive identification strategy to a non-RD IV setting.

This paper formalizes the repeated RD design under the potential outcome framework. We find that, under treatment effect heterogeneity, preserving the recursive CFR strategy to identify long-term average direct effects requires strong assumptions. In the California education bond application, for example, using the recursive CFR strategy requires the decision of putting forward other bond measures after the focal round to be exogeneous, among other identifying conditions such as path-independency and homogeneity in bond effects. As [Dong](#page-26-0) [\(2019\)](#page-26-0) points out in a study of RD design with sample selection, although RD models could be regarded as local random experiments, such randomness around running variable cutoffs could not be used to argue for the ignorance of endogenous selection into RD events. In the dynamic RD design, random participation in subsequent rounds of RD is rarely plausible. Homogeneity in average effects across different RD rounds and regardless of past treatment paths is also very strong.

Given the aforementioned considerations, the main contribution of this paper is to propose a new identification strategy for long-term average direct effects. In contrast to recursive CFR, our proposed identification strategy does not impose any restriction on potentially endogenous RD participation decisions. Our strategy also allows treatment effects to depend on last period's treatment take-up. Our key identification restriction is a conditional mean independence assumption (CIA) that requires mean independence between the second-round running variable and the second-round potential outcomes *without* the second-round treatment, conditional on RD participation. For tractability in longer-term effect identification, we also impose a Markovian-type assumption to simplify the path-dependency structure of average treatment effects. Besides point identification, we provide partial identification results in the Supplemental Appendix [\(Hsu and Shen](#page-27-0) [\(2024\)](#page-27-0)) under Manski-type (e.g., [Manski and Pepper](#page-28-0) [\(2000\)](#page-28-0)) monotonicity conditions.

Our paper relates to the dynamic treatment effect literature outside the RD setting. As [Han](#page-27-0) [\(2021\)](#page-27-0) discusses, the biostatistics literature (e.g., [Robins](#page-28-0) [\(1986,](#page-28-0) [1987\)](#page-28-0), [Murphy,](#page-28-0) [van der Laan, Robins, and C. P. P. R. Group](#page-28-0) [\(2001\)](#page-28-0), [Murphy](#page-28-0) [\(2003\)](#page-28-0), [Chakraborty and Mur](#page-25-0)[phy](#page-25-0) [\(2014\)](#page-25-0)) has a long history of studying dynamic causal effects under the assumption of sequential randomization. As we shall explain in the paper, although sharp RD designs are often understood as local random experiments, the dynamic RD set-up does not enjoy sequential randomization by design. In addition, imposing sequential randomization or ignorability (e.g., [Blackwell](#page-24-0) [\(2013\)](#page-24-0), [Imai and Ratkovic](#page-27-0) [\(2015\)](#page-27-0), [Imbens and](#page-27-0) [Lemieux](#page-27-0) [\(2008\)](#page-27-0), [Bojinov, Rambachan, and Shephard](#page-24-0) [\(2021\)](#page-24-0)) on treatments as an identification condition can be undesirable in empirical RD studies.

Our paper relates to [Heckman, Humphries, and Veramendi](#page-27-0) [\(2016\)](#page-27-0) who evaluate treatment effects in ordered and unordered multistage decision problems with an instrumental variable approach, to [Sun and Abraham](#page-28-0) [\(2021\)](#page-28-0), [Callaway and Sant'Anna](#page-24-0) [\(2021\)](#page-24-0), and [Athey and Imbens](#page-24-0) [\(2022\)](#page-24-0) who examine treatment effects in panel event studies with one single irreversible treatment, to [De Chaisemartin and d'Haultfoeuille](#page-26-0) [\(2020\)](#page-26-0) who study linear two-way fixed-effect regressions for panel data models with treatment effect heterogeneity across groups or over time, and to [De Chaisemartin and d'Hault](#page-26-0)[foeuille](#page-26-0) [\(2024\)](#page-26-0) who investigate path-specific long-term average treatment effects using the parallel trend condition. All aforementioned papers have different model set-ups and identifying assumptions than ours. [Han](#page-27-0) [\(2021\)](#page-27-0) proposes to identify path-specific ATEs using a sequence of dynamic treatment selection equations and excluded instruments. We do not have natural instruments in the repeated RD setting.

Our dynamic RD model also relates to RD models with repeated designs or multiple scores/cutoffs, including [Grembi, Nannicini, and Troiano](#page-26-0) [\(2016\)](#page-26-0) who propose a difference-in-discontinuities strategy to partial out the effect of a confounding policy, [Lv, Sun, Lu, and Li](#page-27-0) [\(2019\)](#page-27-0) who consider RD survival analysis where individual treatments are allowed to be allocated at different pre-treatment duration, multiscore models studied by [Papay, Willett, and Murnane](#page-28-0) [\(2011\)](#page-28-0), [Reardon and Robinson](#page-28-0) [\(2012\)](#page-28-0), and [Wong,](#page-28-0) [Steiner, and Cook](#page-28-0) [\(2013\)](#page-28-0), and the multicutoff RD model of [Cattaneo, Keele, Titiunik, and](#page-25-0) [Vazquez-Bare](#page-25-0) [\(2016\)](#page-25-0). Given our focus on long-term direct effects, this paper is significantly different from the others.

Aside from identification, our paper contributes to the literature by designing a new two-step semiparametric boundary estimation procedure. Specifically, our identified long-term effects has a form of inverse propensity score weighting (IPW), and so the estimation follows two steps. In the first step, we model the propensity score function semiparametrically and estimate it with the local MLE approach in [Cai, Fan, and Li](#page-24-0) [\(2000\)](#page-24-0). In the second step, we plug in estimated propensity scores to local-linear regressions. Our proposed first-step local MLE algorithm is particularly suitable for the RD setting, because it allows the propensity score estimator to stay local to the RD cutoff along the dimension of the running variable (cf. [Gelman and Imbens](#page-26-0) [\(2019\)](#page-26-0)) while not overburdening the final two-step estimator with the "curse of dimensionality." In terms of inference, our paper is the first to apply the weighted bootstrap designed in [Ma and](#page-28-0) [Kosorok](#page-28-0) [\(2005\)](#page-28-0) to kernel-based boundary estimation, which is the main workhorse of the RD literature. The weighted bootstrap method has also been adopted by [Chen and](#page-25-0) [Pouzo](#page-25-0) [\(2009\)](#page-25-0), Chernozhukov, Fernández-Val, Hoderlein, Holzmann, and Newey [\(2015\)](#page-25-0), [Chernozhukov, Fernández-Val, and Kowalski](#page-25-0) [\(2015\)](#page-25-0), and [Fernández-Val, van Vuuren,](#page-26-0) [and Vella](#page-26-0) [\(2021\)](#page-26-0), among others, in other estimation settings.

The rest of the paper is organized as follows. Section 2 starts with a simple twoperiod dynamic RD model, explaining why long-term direct effects are important policy parameters and why their identification cannot be obtained directly from the RD design. Section [2.2](#page-6-0) formalizes the recursive CFR identification strategy under treatment effect heterogeneity and discuss its limitations. Sections [2.3](#page-8-0) and [2.4](#page-11-0) present a new identification and estimation strategy for the one-period-after average direct effect in the benchmark two-period model. Section [3](#page-12-0) presents the general multiperiod dynamic RD model and the identification of longer-term average direct effects. Section [4](#page-16-0) studies estimation and inference of the general model. Section [5](#page-21-0) revisits the empirical study of California education bonds using CFR's published data set. Section [6](#page-24-0) concludes. Monte Carlo simulations and proofs are provided in the Supplemental Appendix, which also includes partial identification results and several empirical-relevant special cases.

2. A BENCHMARK TWO-PERIOD MODEL

In this section, we use a simple two-period model to define the dynamic RD design under the potential outcome framework. We take the simple model to point out complications brought by having a repetition in the RD design, as well as the differences between dynamic RD models and other non-RD dynamic models previously studied in the literature. We propose a novel identification strategy in this two-period model and discuss its advantages compared to previous methods.

Before we begin, it is important to point out that the simple two-period model defined in this section is only a starting point. Some important identification results provided in this paper are only relevant for the general case presented in Section [3.](#page-12-0)

2.1 *The classic potential outcome framework*

Consider a repeated RD setting, where the RD event (e.g., election, testing, etc.) takes place *at the beginning* of each period, and the treatment is administrated immediately following the event for participants who pass a running variable threshold. An outcome is observed *at the end* of each period.

In period one, we assume for now that everyone takes part in the RD event, so the *observed* treatment D_{i1} and outcome Y_{i1} of individual *i* satisfy

$$
D_{i1} = 1(Z_{i1} \ge 0), \qquad Y_{i1} = Y_{i1}(0) \cdot (1 - D_{i1}) + Y_{i1}(1) \cdot D_{i1},
$$

where Z_{i1} is the first-round running variable and $Y_{i1}(d_1)$ is the *potential* first-period outcome with $D_{i1} = d_1$, for $d_1 = 0$, 1. Without loss of generality, all RD cutoffs in this paper are normalized to zero.

In period two, the potential outcome framework gives

$$
D_{i2} = D_{i2}(0) \cdot (1 - D_{i1}) + D_{i2}(1) \cdot D_{i1}, \text{ and}
$$

\n
$$
Y_{i2} = Y_{i2}(0, 0) \cdot (1 - D_{i1}) \cdot (1 - D_{i2}(0)) + Y_{i2}(0, 1) \cdot (1 - D_{i1}) \cdot D_{i2}(0)
$$

\n
$$
+ Y_{i2}(1, 0) \cdot D_{i1} \cdot (1 - D_{i2}(1)) + Y_{i2}(1, 1) \cdot D_{i1} \cdot D_{i2}(1)
$$

\n
$$
\equiv \sum_{\ell^2 \in \mathcal{L}^2} Y_{i2}(\ell^2) \cdot \mathfrak{D}_i(\ell^2), \quad \mathcal{L}^2 = \{(0, 0), (0, 1), (1, 0), (1, 1)\},
$$

where D_{i2} and Y_{i2} are *observed* treatment decisions and outcomes, while $D_{i2}(d_1)$ and $Y_{i2}(d_1, d_2)$, $d_1, d_2 = 0, 1$, are their *potential* counterparts. $\mathfrak{D}_i(.)$ is the path indicator of individual i and \mathcal{L}^2 is the set of all possible treatment paths in two periods. This dynamic potential outcome framework is common in dynamic causal effect settings outside RD. See, for example, Section III of the biostatistics textbook [Hernán and Robins](#page-27-0) [\(2023\)](#page-27-0) and previous work in econometrics, including [Hahn, Todd, and van der Klaauw](#page-27-0) [\(2001\)](#page-27-0) and [Bojinov, Rambachan, and Shephard](#page-24-0) [\(2021\)](#page-24-0).

The RD setting also brings special features to the dynamic model. Specifically, the second-period treatment decision $D_{i2}(d_1)$ is determined by a potentially endogenous RD participation indicator $S_{i2}(d_1)$ and a potentially endogenous second-round running variable $Z_{i2}(d_1)$ such that $D_{i2}(d_1) = S_{i2}(d_1) \cdot 1(Z_{i2}(d_1) \ge 0)$. The second-period *observed* participation decision and treatment decision satisfy

$$
S_{i2} = S_{i2}(0) \cdot (1 - D_{i1}) + S_{i2}(1) \cdot D_{i1},
$$

\n
$$
D_{i2} = S_{i2}(0) \cdot 1(Z_{i2}(0) \ge 0) \cdot (1 - D_{i1}) + S_{i2}(1) \cdot 1(Z_{i2}(1) \ge 0) \cdot D_{i1}.
$$

The second-round running variable $Z_{i2} = Z_{i2}(0) \cdot (1 - D_{i1}) + Z_{i2}(1) \cdot D_{i1}$ is only observed given RD participation, that is, $S_{i2} = 1$.

Example (California Education Bonds). In the California education bond example studied in CFR, outcome measures include local education expenditures, house prices, student achievements, etc. A bond measure is approved if its vote share exceeds the legislative cutoff (normalized to (0). No matter whether a school district gets its bond approved in the first round (D_{i1}) or not, it could choose to initiate a new bond measure in the next election year $(S_{i2} = 1)$ and choose how much campaign efforts to put into the new measure to improve its vote share result $(Z_{i2}(d_1)$, for $d_1 = 0, 1$.

We formally define the following *individual* treatment effects for the two-period model:

immediate effect of D_{i1} : $\theta_{i:0,1} = Y_{i1}(1) - Y_{i1}(0);$ immediate effect of D_{i2} : $\theta_{i;0,2}^{d_1} = Y_{i2}(d_1,1) - Y_{i2}(d_1,0)$, *for* $d_1 = 0,1$; one-period-after direct effect of D_{i1} : $\theta_{i;1,1} = Y_{i2}(1, 0) - Y_{i2}(0, 0);$ one-period-after total effect of D_{i1} : $\theta_{i;1,1} = Y_{i2}(1) - Y_{i2}(0)$, $where \ Y_{i2}(d_1) \equiv Y_{i2}(d_1, D_{i2}(d_1)) = Y_{i2}(d_1, 0)(1 - D_{i2}(d_1)) + Y_{i2}(d_1, 1)D_{i2}(d_1).$

Note that the immediate effect of the second-round treatment is path-dependent. Following [Heckman, Humphries, and Veramendi](#page-27-0) [\(2016\)](#page-27-0) and CFR, we define long-term direct effects by prohibiting treatment take-ups after the focal round. The total effect, on the other hand, does not limit treatment decisions after the focal round. Direct and to-tal effects are also commonly seen in the mediation literature.¹ See [Huber](#page-27-0) [\(2020\)](#page-27-0) for a literature review.

Assumption 2.1. *There exists an* $\epsilon > 0$, *such that*:

- 1. Z_{i1} *is continuous in* $z_1 \in (-\epsilon, \epsilon) \equiv \mathcal{N}_{\epsilon}$ *with* $P[Z_{i1} \ge 0] \in (0, 1)$;
- 2. $E[Y_{i1}(d_1)|Z_{i1} = z_1]$, $E[D_{i2}(d_1)|Z_{i1} = z_1]$, and $E[Y_{i2}(d_1)|Z_{i1} = z_1]$ are all continuous *in* $z_1 \in \mathcal{N}_{\epsilon}$, *for both* $d_1 = 0, 1$.

Assumption 2.1 imposes traditional RD smoothness conditions that provide identification for the average immediate effect $E[\theta_{i;0,1}|Z_{i1} = 0]$ and the average first-stage effect $E[D_{i2}(1) - D_{i2}(0)|Z_{i1} = 0]$. Since the random variable $Y_{i2}(d_1)$, which takes place in the second period but only specifies the first-round treatment status, can be viewed

¹In the mediation literature, $\theta_{i;1,1} = Y_{i;2}(1,0) - Y_{i;2}(0,0)$ is the controlled direct effect, in contrast to the pure direct effect, which would be $Y_{i2}(1, D_{i2}(0)) - Y_{i2}(0, D_{i2}(0))$ in our notation. [Flores and Flores-Lagunes](#page-26-0) [\(2009,](#page-26-0) [2010\)](#page-26-0) study the pure direct effect in the econometrics literature. As [Huber](#page-27-0) [\(2020\)](#page-27-0) discusses, the pure direct effect is not interesting in the dynamic setting.

as a potential outcome of the first-round treatment, smoothness conditions in Assumption [2.1](#page-5-0) also identifies the average one-period-after total effect:

$$
E[\tilde{\theta}_{i;1,1}|Z_{i1} = z_1] = E[\tilde{Y}_{i2}(1) - \tilde{Y}_{i2}(0)|Z_{i1} = 0]
$$

=
$$
\lim_{z_1 \searrow 0} E[Y_{i2}|Z_{i1} = z_1] - \lim_{z_1 \nearrow 0} E[Y_{i2}|Z_{i1} = z_1].
$$
 (2.1)

In the rest of Section [2,](#page-3-0) we explore conditions that identify the average direct effect $E[\theta_{i,1,1}|Z_{i1} = 0]$, which has important policy implications as argued in [Heckman and](#page-27-0) [Navarro](#page-27-0) [\(2007\)](#page-27-0) and CFR. For conciseness, we call $E[\theta_{i:1,1}|Z_{i1} = 0]$ the one-period-after ATE. It has the following relationship with the one-period-after average total effect:

$$
E[\tilde{\theta}_{i;1,1}|Z_{i1} = 0] = E[\theta_{i;1,1}|Z_{i1} = 0] + E[\theta_{i;0,2}^{1}D_{i2}(1)|Z_{i1} = 0] - E[\theta_{i;0,2}^{0}D_{i2}(0)|Z_{i1} = 0].
$$
\n(2.2)

Example (continued). In the California education bond example, the one-period-after ATE $(E[\theta_{i:1,1}|Z_{i1} = 0])$ is the average effect of passing an education bond in the first period on the second-period outcome with no bond authorization after the first period, among all school districts at the first-period vote share cutoff. The one-period-after ATE influences the one-period-after average total effect $(E[\tilde{\theta}_{i;1,1}|Z_{i1} = 0])$, which is identified by the period two outcome discontinuity observed at the period one vote share cutoff. However, the one-period-after total effect is also influenced by the fact that school districts can pass new bond measures in the second period, and hence receive immediate effects from those additional treatments.

2.2 *Recursive identification strategy in CFR*

CFR propose a recursive identification strategy for long-term direct effects based on an implicit treatment effect homogeneity assumption, which requires individual treatment effects to vary only by the number of periods between potential outcomes and the focal round of treatment.² For the two-period model, that is to require

$$
\theta_0 \equiv \theta_{i,0,1} = \theta_{i,0,2}^0 = \theta_{i,0,2}^1
$$
 and $\theta_1 \equiv \theta_{i,1,1}$ for all *i*, (2.3)

where θ_0 and θ_1 are unknown fixed parameters.

The strong assumption reduces the relationship in (2.2) to

$$
E[\tilde{\theta}_{i;1,1}|Z_{i1}=0]=\theta_1+\theta_0E[D_{i2}(1)-D_{i2}(0)|Z_{i1}=0].
$$

The simplification implies recursive identification of the one-period-after ATE θ_1 , since all other components of the equation are directly identifiable through smoothness conditions.

CFR's recursive strategy can be extended to allow for individual treatment effect heterogeneity under the potential outcome framework outlined in the previous section.

²See, for example, Section IV.B of CFR. In CFR, our direct effect is called the "treatment-on-the-treated" effect and our total effect is called the "intent-to-treat" effect.

Lemma 2.1. *Under Assumption* [2.1,](#page-5-0) *the homogeneous ATE requirement*:

$$
ATE_0 \equiv E[\theta_{i;0,1} | Z_{i1} = 0] = E[\theta_{i;0,2}^1 | Z_{i1} = 0] = E[\theta_{i;0,2}^0 | Z_{i1} = 0],
$$
\n(2.4)

and the random second-round treatment selection requirement:

$$
E\big[\theta_{i;0,2}^{d_1}|D_{i2}(d_1), Z_{i1} = 0\big] = E\big[\theta_{i;0,2}^{d_1}|Z_{i1} = 0\big], \quad d_1 = 0, 1,
$$
\n(2.5)

the recursive identification strategy in CFR can be preserved:

$$
\begin{aligned} \text{ATE}_0 &= \lim_{z_1 \searrow 0} E[Y_{i1} | Z_{i1} = z_1] - \lim_{z_1 \nearrow 0} E[Y_{i1} | Z_{i1} = z_1], \\ \text{ATE}_1 &= E[\theta_{i;1,1} | Z_{i1} = 0] = \lim_{z_1 \searrow 0} E[Y_{i2} | Z_{i1} = z_1] - \lim_{z_1 \nearrow 0} E[Y_{i2} | Z_{i1} = z_1] \\ &- \text{ATE}_0 \cdot \Big(\lim_{z_1 \searrow 0} E[D_{i2} | Z_{i1} = z_1] - \lim_{z_1 \nearrow 0} E[D_{i2} | Z_{i1} = z_1] \Big). \end{aligned}
$$

To preserve CFR's recursive identification strategy under individual treatment effect heterogeneity, conditions (2.4) and (2.5) are required. The conditions include the strong homogeneity assumption in (2.3) as a special case.³If the homogeneity ATE condition in (2.4) is violated due to diminishing marginal returns to repeated treatments (i.e., $E[\theta_{i;0,2}^1 | Z_{i1} = 0] < E[\theta_{i;0,2}^0 | Z_{i1} = 0] = E[\theta_{i;0,1} | Z_{i1} = 0]$), then ATE₁ identified in Lemma 2.1 is smaller than the true value of $E[\theta_{i+1}|Z_i] = 0$.

The random treatment selection condition in (2.5) should not to be confused with the local randomness intuition of the RD design. A treatment intervention satisfying the sharp RD design is only *locally* random at its *own* running variable cutoff. In other words, the RD design associated with $D_{i2}(d_1)$ only indicates local randomness among individuals at $Z_{i2}(d_1) = 0$, for $d_1 = 0$, 1. Equation (2.5) is different. It is not implied by the RD design and is a strong condition used to obtain the recursive identification result.

Example (continued). In the California education bond example, data reveal that school districts barely passing their education bond in the first round do not put forward another bond in the second period (i.e., $E[S_{i2}(1)|Z_{i1} = 0] = \lim_{z_1 \searrow 0} E[S_{i2}|Z_{i1} = z_1] = 0$). Therefore, equation (2.5) essentially restricts that, for a school district *i* that marginally failed the first-round voting, the decision of putting forward another measure in the next election cycle $(S_{i2}(0))$ is not related to the immediate treatment effect of the new

$$
E\big[\theta_{i;0,2}^{d_1}|D_{i2}(d_1), X_i = x, Z_{i1} = 0\big] = E\big[\theta_{i;0,2}^{d_1}|X_i = x, Z_{i1} = 0\big], \text{ and}
$$
\n
$$
\text{CATE}_0(x) = E\big[\theta_{i;0,1}|X_i = x, Z_{i1} = 0\big]
$$
\n
$$
(2.6)
$$

$$
=E\big[\theta_{i;0,2}^{d_1}|X_i=x,Z_{i1}=0\big],\quad\forall d_1=0,\,1,\,x\in\mathcal{X}.\tag{2.7}
$$

 $3A$ more general multiperiod version of the lemma is discussed in the Supplemental Appendix, where we also extend Lemma 2.1 to include conditioning covariates $X_i \in \mathcal{X}$. The extension replaces the homogeneous ATE assumption in (2.4) and the random treatment selection assumption in (2.5) with

measure $(\theta_{i;0,2}^0)$. The equation also implies that, conditional on putting forward another measure ($S_{i2}(0) = 1$), the amount of resources devoted toward campaigning to improve the second-round vote share $(Z_{i2}(0))$ is not related to the immediate treatment effect $(\theta_{i,0,2}^0)$ either. If school districts with higher $\theta_{i,0,2}^0$'s are more likely to pass their second-round measures, $ATE₁$ identified by Lemma [2.1](#page-7-0) is smaller than the true value of $E[\theta_{i;1,1}|Z_{i1} = 0].$

The recursive identification structure of Lemma [2.1](#page-7-0) is to be distinguished from the one-step approach commonly seen in the biostatistics literature (e.g., [Hernán and](#page-27-0) [Robins](#page-27-0) [\(2023\)](#page-27-0)). To see this, we note that an alternative way of imposing randomization on D_{i2} is to rule out the possibility that individuals endogenously choose D_{i2} based on how quickly the effect of D_{i1} dies out over time. In such a case, ATE₁ could be identified in one step as $\lim_{z_1\searrow 0} E[Y_{i2}|D_{i2} = 0, Z_{i1} = z_1] - \lim_{z_1\nearrow 0} E[Y_{i2}|D_{i2} = 0, Z_{i1} = z_1]$ (or a more robust version allowing for conditioning covariates). In many empirical applications including the California education bond example, it is likely more plausible to assume that D_{i2} is exogenous to its own immediate effect as in [\(2.5\)](#page-7-0) than to assume that D_{i2} is irrelevant to the long-run effect of D_{i1} , hence favoring the recursive identification strategy proposed by CFR. Having said that, condition [\(2.5\)](#page-7-0) is still potentially strong. In the following sections, we seek to relax both identifying conditions [\(2.4\)](#page-7-0) and [\(2.5\)](#page-7-0) required in Lemma [2.1.](#page-7-0)

2.3 *Proposed identification strategy*

In this section, we propose a new identification strategy for the one-period-after ATE. Compared to Lemma [2.1,](#page-7-0) the new method imposes no restrictions on the potentially endogenous second-round RD participation decision. In addition, the new strategy allows for arbitrary path-dependency in the second-round immediate effect.

ASSUMPTION 2.2. *There exists* $\epsilon > 0$ *such that for both* d_1 , $d_2 = 0$, 1:

- 1. (*CIA*) $E[Y_{i2}(d_1, 0)|Z_{i2}(d_1) = z_2, S_{i2}(d_1) = 1, Z_{i1} = z_1] = E[Y_{i2}(d_1, 0)|S_{i2}(d_1) = 1,$ $Z_{i1} = z_1$ *for all* $z_1 \in \mathcal{N}_{\epsilon}$;
- 2. (*Smoothness*) $E[Y_{i2}(d_1, d_2)|D_{i2}(d_1) = d_2, Z_{i1} = z_1]$ and $E[D_{i2}(d_1)|S_{i2}(d_1) = 1, Z_{i1} = z_1]$ z_1] *are both continuous in* $z_1 \in \mathcal{N}_\epsilon$;
- 3. (*Overlapping*) $E[D_{i2}(d_1)|S_{i2}(d_1) = 1, Z_{i1} = z_1] \in (0, 1)$ *for all* $z_1 \in \mathcal{N}_{\epsilon}$.

The key identifying condition of Assumption 2.2 is the first CIA condition. It imposes a mean independence condition on marginal individuals at the first-round RD cutoff who choose to participate in the second-round RD. The CIA condition could be weakened using covariates and observationally equivalent subpopulations. The second and third parts of Assumption 2.2 are standard RD smoothness and overlapping conditions. Section A.4.1 in the Supplemental Appendix discusses an important departure from Assumption 2.2.3 for having an absorbing treatment in the dynamic RD model.

Example (continued). In the California education bond example, the CIA condition in Assumption [2.2](#page-8-0) requires that, should the second-round education bond measure fail, the potential second-period outcome (of a school district at the first-round vote share cutoff) is mean independent of the second-round vote share. Note that the CIA condition is *not* about potential outcomes *with* second-round bond authorization. This is important because, for example, the size of the proposed bond can affect both the vote share and the potential outcome *with* second-round bond approval. The CIA condition also does *not* impose any restriction on the potentially endogenous decision of putting forward a new bond measure in the second period.

By standard RD identification arguments, Assumptions [2.2.](#page-8-0)2 and [2.2.](#page-8-0)3 imply that

$$
E[Y_{i2}(1, 1)|D_{i2}(1) = 1, Z_{i1} = 0] = \lim_{z_1 \searrow 0} E[Y_{i2}|S_{i2} = 1, D_{i2} = 1, Z_{i1} = z_1].
$$

Assumptions [2.2.](#page-8-0)1, [2.2.](#page-8-0)2, and [2.2.](#page-8-0)3 together imply that

$$
E[Y_{i2}(1,0)|D_{i2}(1) = 1, Z_{i1} = 0] = \lim_{z_1 \searrow 0} E[Y_{i2}(1,0)|S_{i2}(1) = 1, Z_{i2}(1) \ge 0, Z_{i1} = z_1]
$$

=
$$
\lim_{z_1 \searrow 0} E[Y_{i2}|S_{i2}(1) = 1, Z_{i2}(1) < 0, Z_{i1} = z_1]
$$

=
$$
\lim_{z_1 \searrow 0} E[Y_{i2}|S_{i2} = 1, D_{i2} = 0, Z_{i1} = z_1],
$$

where the second equality holds by the CIA. Summarizing the above two equations and obtaining a similar result for $d_1 = 0$, we have

$$
E[Y_{i2}(1, d_2)|D_{i2}(1) = 1, Z_{i1} = 0] = \lim_{z_1 \searrow 0} E[Y_{i2}|S_{i2} = 1, D_{i2} = d_2, Z_{i1} = z_1], \quad (2.8)
$$

$$
E[Y_{i2}(0, d_2)|D_{i2}(0) = 1, Z_{i1} = 0] = \lim_{z_1 \nearrow 0} E[Y_{i2}|S_{i2} = 1, D_{i2} = d_2, Z_{i1} = z_1],
$$
 (2.9)

which further imply that

$$
E[\theta_{i;0,2}^1 D_{i2}(1)|Z_{i1} = 0] = \lim_{z_1 \searrow 0} E[Y_{i2}S_{i2}(D_{i2} - \lambda_{D_2|S_2}^1)|Z_{i1} = z_1]/(1 - \lambda_{D_2|S_2}^1),
$$

\n
$$
E[\theta_{i;0,2}^0 D_{i2}(0)|Z_{i1} = 0] = \lim_{z_1 \nearrow 0} E[Y_{i2}S_{i2}(D_{i2} - \lambda_{D_2|S_2}^0)|Z_{i1} = z_1]/(1 - \lambda_{D_2|S_2}^0),
$$

\n
$$
\lambda_{D_2|S_2}^{d_1} = P[D_{i2}(d_1) = 1|S_{i2}(d_1) = 1, Z_{i1} = 0].
$$

Together with the decomposition in [\(2.2\)](#page-6-0), the one-period-after ATE is identified.

The CIA condition in Assumption [2.2](#page-8-0) can be extended to include covariates. Specifically, let $X_i \in \mathcal{X}$ be the vector of covariates. The extended CIA condition is

$$
E[Y_{i2}(d_1, 0)|X_i = x, Z_{i2}(d_1) = z_2, S_{i2}(d_1) = 1, Z_{i1} = z_1]
$$

=
$$
E[Y_{i2}(d_1, 0)|X_i = x, S_{i2}(d_1) = 1, Z_{i1} = z_1], \forall x \in \mathcal{X}.
$$
 (2.10)

The vector of covariates X_i could include both pretreatment controls and first-period outcomes. The role of X_i here is different from that in static RD, where covariates are used to improve estimation efficiency (e.g., [Calonico et al.](#page-25-0) [\(2019\)](#page-25-0)).

Example (continued). Suppose school expenditure is the outcome of interest. The vanilla CIA condition without covariates might not be appropriate if school districts with lower baseline funding levels $(Y_{i2}(d_1, 0))$ are more incentivized to carry out an active campaign, resulting in a higher vote share $(Z_{i2}(d_1))$. A useful conditioning covariate for the extended CIA condition in [\(2.10\)](#page-9-0) is hence the first-period school expenditure $(Y_{i1}(d_1))$. If a district's expenditure without new bond authorization follows an AR(1) process with the random shock in each period being mean independent of the bond vote share, then the extended CIA condition in [\(2.10\)](#page-9-0) holds.

Identification results in [\(2.8\)](#page-9-0) and [\(2.9\)](#page-9-0) could be easily extended to incorporate covariates. Let

$$
\lambda^{d_1}(x) \equiv \lambda_{D_2|S_2}^{d_1}(x) = P[D_{i2}(d_1) = 1 | X_i = x, S_{i2}(d_1) = 1, Z_{i1} = 0], \quad d_1 = 0, 1,
$$

be the propensity score function conditional on second-round RD participation. Strengthen smoothness and overlapping conditions in Assumption [2.2](#page-8-0) to require that, for all $x \in \mathcal{X}$,

$$
E[Y_{i2}(d_1, d_2)|X_i = x, D_{i2}(d_1) = d_2, Z_{i1} = z_1]
$$
 and

$$
E[D_{i2}(d_1)|X_i = x, S_{i2}(d_1) = 1, Z_{i1} = z_1]
$$
 are continuous in $z_1 \in \mathcal{N}_{\epsilon}$, (2.11)

and

$$
E[D_{i2}(d_1)|X_i = x, S_{i2}(d_1) = 1, Z_{i1} = z_1] \in (0, 1) \text{ for all } z_1 \in \mathcal{N}_{\epsilon}.
$$
 (2.12)

The following lemma summarizes identification of the one-period-after ATE using $IPW⁴$

Lemma 2.2. *Under Assumptions* [2.1,](#page-5-0) *and the extended CIA*, *smoothness*, *and overlapping conditions in* [\(2.10\)](#page-9-0), (2.11), *and* (2.12), *the one-period-after ATE is identified*:

$$
E[\theta_{i;1,1}|Z_{i1} = 0] = \alpha^{1} - \alpha^{0}, \quad \text{where}
$$

$$
\alpha^{1} = \lim_{z_{1} \searrow 0} E\bigg[Y_{i2} - \frac{Y_{i2}S_{i2}(D_{i2} - \lambda^{1}(X_{i}))}{1 - \lambda^{1}(X_{i})}\bigg|Z_{i1} = z_{1}\bigg],
$$

$$
\alpha^{0} = \lim_{z_{1} \nearrow 0} E\bigg[Y_{i2} - \frac{Y_{i2}S_{i2}(D_{i2} - \lambda^{0}(X_{i}))}{1 - \lambda^{0}(X_{i})}\bigg|Z_{i1} = z_{1}\bigg].
$$

The proof is provided in the Supplemental Appendix. In the next section, we propose a semiparametric local MLE method (cf. [Cai, Fan, and Li](#page-24-0) [\(2000\)](#page-24-0)) for propensity score estimation. The method will require additional functional form assumptions on

[⁴Angrist, Jordà, and Kuersteiner](#page-24-0) [\(2018\)](#page-24-0) adopted IPW in the static RD model for extrapolating treatment effects away from the running variable cutoff. IPW is also commonly used outside RD, for both crosssectional and dynamic treatment models (e.g., [Blackwell](#page-24-0) [\(2013\)](#page-24-0), [Huber](#page-27-0) [\(2020\)](#page-27-0), [Bojinov, Rambachan, and](#page-24-0) [Shephard](#page-24-0) [\(2021\)](#page-24-0), [Imai, Kim, and Wang](#page-27-0) [\(2023\)](#page-27-0), [Hernán and Robins](#page-27-0) [\(2023\)](#page-27-0), among many others).

the propensity score functions. The semiparametric approach is particularly suitable for the RD setting as it will allow the propensity score estimator to stay local to the RD cutoff along the dimension of the running variable [\(Gelman and Imbens](#page-26-0) [\(2019\)](#page-26-0)) while not overburdening the final ATE estimator with the "curse of dimensionality."

2.4 *Proposed estimation strategy*

Assume that the conditional probability function $P[D_{i2} = 1 | X_i = x, S_{i2} = 1, Z_{i1} = z_1]$ follows a class of semiparametric models $p(x, \gamma(z_1))$, where $p(., .): \mathcal{X} \times \Gamma \to \mathbb{R}$ is known but $\gamma(.) : \mathbb{R} \to \Gamma$ is unknown. For example, $p(x, \gamma(z_1))$ can be a varying coefficient logit model, nesting both parametric logit and semiparametric partial-linear logit as special cases. Let $\gamma^0 = \lim_{z_1 \nearrow 0} \gamma(z_1)$ and $\gamma^1 = \lim_{z_1 \searrow 0} \gamma(z_1)$. Propensity score functions $\lambda^0(x)$ and $\lambda^1(x)$ could be written as $p(x, \gamma^0)$ and $p(x, \gamma^1)$.

Let $\beta_{FS}^0 = \lim_{z_1 \nearrow 0} \nabla \gamma(z_1)$ and $\beta_{FS}^1 = \lim_{z_1 \searrow 0} \nabla \gamma(z_1)$ be the left and the right limits of the gradient of $\gamma(.)$ at the RD cutoff. Let $K(.)$ be the kernel function and h the bandwidth. Let $\hat\gamma^0$, $\hat\gamma^1$, $\hat\beta_{\rm FS}^0$ and $\hat\beta_{\rm FS}^1$ denote estimators of γ^0 , γ^1 , β^0 , and β^1 . They solve the following maximization problems:

$$
(\hat{\gamma}^1, \hat{\beta}_{FS}^1) = \arg \max_{\gamma, \beta} \sum_{i=1}^n S_{2i} 1(Z_{1i} \ge 0) K\left(\frac{Z_{1i}}{h}\right)
$$

$$
\cdot [D_{2i} \log p(X_i, \gamma + \beta Z_{1i}) + (1 - D_{2i}) \log (1 - p(X_i, \gamma + \beta Z_{1i}))],
$$

$$
(\hat{\gamma}^0, \hat{\beta}_{FS}^0) = \arg \max_{\gamma, \beta} \sum_{i=1}^n S_{2i} 1(Z_{1i} < 0) K\left(\frac{Z_{1i}}{h}\right)
$$

$$
\cdot [D_{2i} \log p(X_i, \gamma + \beta Z_{1i}) + (1 - D_{2i}) \log (1 - p(X_i, \gamma + \beta Z_{1i}))].
$$

When $p(x, \gamma(z_1))$ follows a varying coefficient logit model, the optimization problem described above are weighted logit regressions of D_{2i} on X_i , Z_i , and X_iZ_i , with weights determined by $K(Z_{1i}/h)$. Details are provided in Section [4](#page-16-0) for estimation in the general multiperiod case. If the CIA condition in the previous section holds without any conditioning covariates, the first-step estimation is fully nonparametric.

Denote $E[\theta_{i;1,1}|Z_1=0]$ by $\bar{\theta}_{1,1}$ and its estimator by $\bar{\theta}_{1,1}$. Given the above-defined first-step propensity score estimators, $\bar{\theta}_{1,1}$ could be estimated by boundary local linear regressions of generated outcomes on the RD running variable. Specifically,

$$
\hat{\theta}_{1,1} = \hat{\alpha}^1 - \hat{\alpha}^0,
$$

\n
$$
(\hat{\alpha}^1, \hat{\beta}^1) = \arg\min_{\alpha,\beta} \sum_{i=1}^n 1(Z_{1i} \ge 0) K\left(\frac{Z_{1i}}{h}\right) [A_i(\alpha, \beta; \hat{\gamma}^1)]^2,
$$

\n
$$
(\hat{\alpha}^0, \hat{\beta}^0) = \arg\min_{\alpha,\beta} \sum_{i=1}^n 1(Z_{1i} < 0) K\left(\frac{Z_{1i}}{h}\right) [A_i(\alpha, \beta; \hat{\gamma}^0)]^2,
$$

where $A_i(\alpha, \beta; \gamma) = Y_{2i} - \frac{Y_{2i}S_{2i}(D_{2i} - p(X_i, \gamma))}{1 - p(X_i, \gamma)} - \alpha - \beta Z_{1i}$.

Estimators $\hat{\lambda}^0$, $\hat{\lambda}^1$, and $\bar{\theta}_{1,1}$ are all consistent and asymptotically normally distributed under proper assumptions. In the above estimation procedure, the kernel bandwidth is kept the same in both steps. If the bandwidth in the first-step propensity score estimation is chosen to shrink at a slower rate, the first-step estimation error would vanish asymptotically for the two-step estimator, simplifying the asymptotic variance of $\bar{\theta}_{1,1}$. We use the same bandwidth in both steps to save the number of tuning parameters. More details about estimation, as well as a weighted bootstrap inference strategy, will be discussed in Section [4.](#page-16-0)

When the conditioning covariate X_i is nonempty, the proposed estimation procedure is semiparametric. An interesting extension for future research is to extend the firststep propensity score estimation procedure along the lines of high-dimensional covariate selection (cf. [Chernozhukov et al.\(2018\)](#page-25-0)), doubly robust estimation (cf. [Kennedy, Ma,](#page-27-0) [McHugh, and Small](#page-27-0) [\(2017\)](#page-27-0)), or [Fan, Hsu, Lieli, and Zhang](#page-26-0) [\(2022\)](#page-26-0) who combine doubly robust estimation with high-dimensional covariate selection in treatment evaluation.

3. Identification in the general multiperiod setting

3.1 *Set-up*

Let $k = 1, 2, \ldots, K$ denote the round of treatment intervention whose eligibility is determined by an RD design. Let $t = 1, 2, ..., T$ denote the period of observed outcomes, and assume without loss of generality that $T = K$.⁵ Let D_{ik} be the *observed* treatment status of an individual in round k, S_{ik} the *observed* participation indicator, and Z_{ik} the *observed* running variable, which is observed only when $S_{ik} = 1$. Recall from Section [2](#page-3-0) that $S_{i1} = 1$ and $D_{i1} = 1$ ($Z_{i1} \ge 0$). For any $k \ge 2$,

$$
D_{ik} = \sum_{\ell^{k-1} \in \mathcal{L}^{k-1}} D_{ik}(\ell^{k-1}) \cdot \mathfrak{D}_i(\ell^{k-1}) \equiv \sum_{\ell^{k-1} \in \mathcal{L}^{k-1}} S_{ik}(\ell^{k-1}) 1(Z_{ik}(\ell^{k-1}) \ge 0) \cdot \mathfrak{D}_i(\ell^{k-1}),
$$

\n
$$
S_{ik} = \sum_{\ell^{k-1} \in \mathcal{L}^{k-1}} S_{ik}(\ell^{k-1}) \cdot \mathfrak{D}_i(\ell^{k-1}),
$$

\n
$$
Z_{ik} = \sum_{\ell^{k-1} \in \mathcal{L}^{k-1}} Z_{ik}(\ell^{k-1}) \cdot \mathfrak{D}_i(\ell^{k-1}) \quad \text{if } S_{ik} = 1,
$$

where $D_{ik}(\ell^{k-1})$, $S_{ik}(\ell^{k-1})$, and $Z_{ik}(\ell^{k-1})$ are *potential* counterparts (with past treatment path ℓ^{k-1}) of D_{ik} , S_{ik} , and Z_{ik} , respectively. The path indicator $\mathfrak{D}_i(.)$ and set \mathcal{L}^{k-1} extend definitions in Section [2.](#page-3-0) Specifically, the event { $\mathfrak{D}_i(\ell^k) = 1$ } is equivalent to $\{D_{i1} = \ell_1^k, D_{i2}(\ell_1^k) = \ell_2^k, \ldots, D_{ik}(\ell_{1:(k-1)}^k) = \ell_k^k\} = \{D_{i1} = \ell_1^k, D_{i2} = \ell_2^k, \ldots, D_{ik} = \ell_k^k\},\$ where ℓ_j^k ($\ell_{j:j'}^k$) represent the *j*th (*j*th to *j'*th) element(s) of path ℓ^k .

Let Y_{it} be the *observed* outcome in period t and $Y_{it}(\ell^t)$ the potential outcome with past treatment path $\ell^t \in \mathcal{L}^t$ such that

$$
Y_{it} = \sum_{\ell^t \in \mathcal{L}^t} Y_{it}(\ell^t) \cdot \mathfrak{D}_i(\ell^t).
$$

⁵Although in many settings outcomes can be observed in periods after the last round of treatment intervention, for identification purposes it is not necessary to distinguish such longer-term outcomes from outcomes that occur right after the last round of treatment.

Let $\mathbf{0}_\tau$ be a τ -dimensional vector of zeros. Let $\tilde{Y}_{i(k+\tau)}(\ell^k)$ be a $(k+\tau)$ -th period *quasi-potential* outcome, where only the first k rounds of the total $(k + \tau)$ rounds of past treatment status are specified. Specifically, $\tilde{Y}_{i(k+\tau)}(\ell^k) = \sum_{\eta \in \mathcal{L}^\tau} Y_{i(k+\tau)}(\ell^k, \eta) \times$ $\mathfrak{D}_{i;(k+1):(k+\tau)}(\ell^k, \eta)$, where partial path indicator $\{\mathfrak{D}_{i;l'l'}(\ell^k) = 1\} \Leftrightarrow \{D_{il}(\ell^k_{1:(l-1)}) = 1\}$ $\ell_1^k, D_{i(l+1)}(\ell_{1:l}^k) = \ell_{l+1}^k, ..., D_{il'}(\ell_{1:(l'-1)}^k) = \ell_{l'}^k$. Extending definitions in Section [2,](#page-3-0) we have long-term effects of the first-round treatment for all $\tau \geq 1$:

τ-period-after direct effect of Di¹ : θi;τ,1 = Yi(1+^τ)(1, **0**^τ) − Yi(1+^τ)(0, **0**^τ),

τ-period-after total effect of D_{i1} : $\theta_{i; \tau, 1} = Y_{i(1+\tau)}(1) - Y_{i(1+\tau)}(0)$.

In addition, define the following treatment effects of the kth round treatment:

immediate effect of $D_{ik}: \theta_{i;0,k}^{\ell^{k-1}}=Y_k\big(\ell^{k-1},\,1\big)-Y_k\big(\ell^{k-1},\,0\big),$ τ -period-after direct effect of $D_{ik}: \theta_{i;\tau,k}^{\ell^{k-1}} = Y_{i(k+\tau)}(\ell^{k-1}, 1, \mathbf{0}_\tau) - Y_{i(k+\tau)}(\ell^{k-1}, 0, \mathbf{0}_\tau),$ $\tau\text{-period-after total effect of } D_{ik}: \tilde{\theta}_{i;\tau,k}^{\ell^{k-1}} = \tilde{Y}_{i(k+\tau)}\left(\ell^{k-1}, 1\right) - \tilde{Y}_{i(k+\tau)}\left(\ell^{k-1}, 0\right),$

for all $\tau \geq 1$, $k \geq 2$, and past treatment path $\ell^{k-1} \in \mathcal{L}^{k-1}$.

Before concluding this set-up section, we present a lemma that motivates the study of long-term direct effects. The following lemma shows that treatment effects not falling into the categories discussed above, such as $Y_{i2}(1, 1) - Y_{i2}(0, 1)$ or $Y_{i2}(1, 0) - Y_{i2}(0, 1)$, can be obtained from the immediate effects and long-term direct effects defined above.

Lemma 3.1. *The difference between any pair of potential outcomes can be represented by a linear combination of above-defined immediate effects and long-term direct effects*.

3.2 *Identification*

In this section, we seek identification of the τ -period-after ATE, or $E[\theta_{i;\tau,1}|Z_1 = 0]$, for all $\tau \geq 2$. Following discussions in Section [2,](#page-3-0) we continue to impose no assumptions on subsequent RD participation decisions, which could be potentially endogenous.

Just as in the simple two-period model, our proposed identification strategy is built upon a decomposition of long-term average total effects. The decomposition shows that any long-term total effect is equal to its corresponding direct effect plus a sum of various shorter-term total effects adjusted by subsequent round first-stage treatment decisions:

$$
\tilde{\theta}_{i;\tau,1} = \theta_{i;\tau,1} + \left(\tilde{\theta}_{i;\tau-1,2}^{1} \cdot D_{i2}(1) - \tilde{\theta}_{i;\tau-1,2}^{0} \cdot D_{i2}(0)\right) \n+ \sum_{s=1}^{\tau-2} \left(\tilde{\theta}_{i;s,\tau+1-s}^{(1,0_{\tau-1-s})} \cdot D_{i(\tau+1-s)}(1,0_{\tau-1-s}) - \tilde{\theta}_{i;s,\tau+1-s}^{(0,0_{\tau-1-s})} \cdot D_{i(\tau+1-s)}(0,0_{\tau-1-s})\right) \n+ \theta_{i;0,\tau+1}^{(1,0_{\tau-1})} \cdot D_{i(\tau+1)}(1,0_{\tau-1}) - \theta_{i;0,\tau+1}^{(0,0_{\tau-1})} \cdot D_{i(\tau+1)}(0,0_{\tau-1}).
$$
\n(3.1)

When $\tau = 2$, the decomposition reduces to

$$
\tilde{\theta}_{i;2,1} = \theta_{i;2,1} + \tilde{\theta}_{i;1,2}^1 D_{i2}(1) - \tilde{\theta}_{i;1,2}^0 D_{i2}(0) + \theta_{i;0,3}^{(1,0)} D_{i3}(1,0) - \theta_{i;0,3}^{(0,0)} D_{i3}(0,0).
$$
 (3.2)

The decomposition is new to the literature, as far as the authors know. It is different from the decomposition used behind the recursive CFR identification strategy, where the long-term total effect is decomposed to its corresponding direct effect plus a sum of various shorter-term *direct* effects adjusted by first-stage treatment decisions.⁶ In the rest of the section, we use equation [\(3.1\)](#page-13-0) to develop an identification strategy because the new decomposition involves much fewer path-dependent treatment effects in its formulation.

Aside from utilizing the new decomposition result, we impose a Markovian-type condition to further reduce the number of path-dependent treatment effect parameters involved in identification. Let $\eta_{i;0,1}$, $\eta_{i;0,k}^{\ell^{k-1}}$, $\eta_{i;\tau,1}$, $\eta_{i;\tau,k}^{\ell^{k-1}}$, $\tilde{\eta}_{i;\tau,k}$, and $\tilde{\eta}_{i;\tau,k}^{\ell^{k-1}}$ be firststage counterparts of immediate effects $\theta_{i;0,1}$ and $\theta_{i;0,k}^{\ell^{k-1}}$, direct effects $\theta_{i;\tau,1}$ and $\theta_{i;\tau,k}^{\ell^{k-1}},$ and total effects $\tilde{\theta}_{i;\tau,1}$ and $\tilde{\theta}_{i;\tau,k}^{e^{k-1}}$, respectively.⁷ The following assumption summarizes the identifying restrictions used in the general multiperiod dynamic RD model.

Assumption 3.1 (Longer-term ATEs). *There exists* $\epsilon > 0$ *such that for all* $z_1 \in \mathcal{N}_{\epsilon}$, we *have*:

- 1. (*Markovian*) *for any* $k = 3, 4, ..., K$, $\ell^{k-2} \in \mathcal{L}^{k-2}$, *and* $d = 0, 1$, *immediate effects* and τ -period-after total effects satisfy that $E[\theta_{i;0,k}^{(\ell^{k-2},d)}|D_{ik}(\ell^{k-2},d)=1,Z_{i1}=z_1]=$ $E[\theta_{i;0,2}^d|D_{i2}(d) = 1, Z_{i1} = z_1] \equiv \mu_0^d$ and $E[\tilde{\theta}_{i;\tau,k}^{(\ell^{k-2},d)}|D_{ik}(\ell^{k-2},d) = 1, Z_{i1} = z_1] =$ $E[\tilde{\theta}^d_{i;\tau,2}|D_{i2}(d)=1,Z_{i1}=z_1]\equiv\tilde{\mu}^d_\tau,$ for all $\tau=1,\ldots,K-k;$ similar conditions also *hold for immediate and long-term first-stage effects*;
- 2. (*CIA*: *multiperiod*) *for any* $d_1 = 0, 1, z_2 \in \mathbb{R}$, and $x \in \mathcal{X}$, $E[M_i(d_1, 0)|X_i = x, Z_{i2}(d_1) =$ z_2 , $S_{i2}(d_1) = 1$, $Z_{i1} = z_1$] = $E[M_i(d_1, 0)|X_i = x, S_{i2}(d_1) = 1, Z_{i1} = z_1]$, where the ran*dom variable* $M_i(d_1, 0)$ *can be* $D_{i3}(d_1, 0)$, $Y_{i(2+\tau)}(d_1, 0)$ *for all* $\tau = 1, ..., K - 2$, *or* $D_{i(3+\tau)}(d_1, 0)$ for all $\tau = 1, ..., K-3;$
- 3. (*Smoothness: multiperiod*) *for all* $d_1, d_2 = 0, 1$ *, and* $x \in \mathcal{X}$ *,* $E[M_i(d_1, d_2)|X_i =$ $x, D_{i2}(d_1) = d_2, Z_{i1} = z_1$ *is continuous in* z_1 *, where the random variable* $M_i(d_1, d_2)$ *can be* $D_{i3}(d_1, d_2)$, $Y_{i(2+\tau)}(d_1, d_2)$ *for all* $\tau = 1, ..., K - 2$, *or* $D_{i(3+\tau)}(d_1, d_2)$ *for all* $\tau = 1, \ldots, K - 3;$

The second and third parts of Assumption 3.1 are vanilla extensions of Assump-tion [2.2](#page-8-0) viewing $D_{i3}(d_1, d_2)$, $Y_{i(2+\tau)}(d_1, d_2)$, and $D_{i(2+\tau)}(d_1, d_2)$ as potential outcomes associated with the first two treatments but taking place in a later period. The key new

⁶When $\tau = 2$, for example, the decomposition underlying the recursive CFR identification strategy is $\tilde{\theta}_{i;2,1} = \theta_{i;2,1} + \theta_{i;1,2}^1 D_{i2}(1) + \theta_{i;0,3}^{(1,0)} (1 - D_{i2}(1)) D_{i3}(1,0) + \theta_{i;0,3}^{(1,1)} D_{i2}(1) D_{i3}(1,1) - \theta_{i;1,2}^0 D_{i2}(0) - \theta_{i;0,3}^{(0,0)} (1 - D_{i2}(1)) D_{i3}(1,0)$ $D_{i2}(0)$) $D_{i3}(0,0) + \theta_{i;0,3}^{(0,1)} D_{i2}(0) D_{i3}(0,1).$

⁷Let $\tilde{D}_{i(k+1+\tau)}(\ell^k)$ be the $(k+1+\tau)$ -th period quasi-potential treatment decision with only the first k rounds of previous treatment status specified, for any $\tau \ge 1$ and $k \ge 1$. Then $\eta_{i;0,1} = D_{i2}(1) - D_{i2}(0)$, $\eta_{i;\tau,1} = D_{i(2+\tau)}(1,\mathbf{0}_{\tau}) - D_{i(2+\tau)}(0,\mathbf{0}_{\tau})$, and $\tilde{\eta}_{i;\tau,1} = \tilde{D}_{i(2+\tau)}(1) - \tilde{D}_{i(2+\tau)}(0)$ for all $\tau \geq 1$. For all $k \geq$ $2, \eta_{i;0,k}^{e^{k-1}} = D_{i(k+1)}(\ell^{k-1}, 1) - D_{i(k+1)}(\ell^{k-1}, 0), \eta_{i;\tau,k}^{e^{k-1}} = D_{i(k+1+\tau)}(\ell^{k-1}, 1, \mathbf{0}_{\tau}) - D_{i(k+1+\tau)}(\ell^{k-1}, 0, \mathbf{0}_{\tau}),$ and $\tilde{\eta}_{i;\tau,k}^{\ell^{k-1}} = \tilde{D}_{i(k+1+\tau)}(\ell^{k-1}, 1) - \tilde{D}_{i(k+1+\tau)}(\ell^{k-1}, 0)$ for all $\tau \ge 1$.

condition in Assumption [3.1](#page-14-0) is the Markovian restriction. In the California education bond application, the Markovian restriction allows an education bond's various immediate and long-term average effects to depend arbitrarily on last election cycle's bond authorization but not any other bond authorizations further in the past. Although nontrivial, the Markovian condition is much less restrictive than the homogeneous ATE condition used in Lemma [2.1](#page-7-0) (or Lemma A.1) for the recursive CFR identification strategy.

Similar Markovian-type restrictions are also used in [De Chaisemartin and d'Hault](#page-26-0)[foeuille](#page-26-0) [\(2024\)](#page-26-0) and [Imai, Kim, and Wang](#page-27-0) [\(2023\)](#page-27-0) for non-RD dynamic treatment effect settings. When $\tau = 2$, the Markovian assumption together with the decomposition in [\(3.2\)](#page-13-0) imply that

$$
E[\tilde{\theta}_{i;2,1}|Z_{i1}=0] = E[\theta_{i;2,1}|Z_{i1}=0] + \tilde{\mu}_1^1 \cdot E[D_{i2}(1)|Z_{i1}=0] - \tilde{\mu}_1^0 \cdot E[D_{i2}(0)|Z_{i1}=0] + \mu_0^0 \cdot E[\eta_{i;1,1}|Z_{i1}=0].
$$

Lemma 3.2. *Under the assumptions used in Lemma* [2.2,](#page-10-0) *Assumption A*.1 *for identifying* $long\text{-}term$ average total effects, and Assumption [3.1,](#page-14-0) we have that for $\tau = 2, \ldots, K - 1$,

$$
E[\theta_{i;\tau,1}|Z_{i1} = 0] = \lim_{z_1 \searrow 0} E[Y_{i(\tau+1)}|Z_{i1} = z_1] - \lim_{z_1 \nearrow 0} E[Y_{i(\tau+1)}|Z_{i1} = z_1]
$$

$$
- \tilde{\mu}_{\tau-1}^1 \cdot \lim_{z_1 \searrow 0} E[D_{i2}|Z_{i1} = z_1] + \tilde{\mu}_{\tau-1}^0 \cdot \lim_{z_1 \nearrow 0} E[D_{i2}|Z_{i1} = z_1]
$$

$$
- \sum_{s=1}^{\tau-2} \tilde{\mu}_s^0 \cdot E[\eta_{i;\tau-1-s,1}|Z_{i1} = 0] - \mu_0^0 \cdot E[\eta_{i;\tau-1,1}|Z_{i1} = 0], \quad (3.3)
$$

where

$$
\mu_0^0 = \lim_{z_1 \nearrow 0} E\bigg[\frac{Y_{i2}S_{i2}(D_{i2} - \lambda^0(X_i))}{(1 - \lambda^0(X_i))E[D_{i2}|Z_{i1} = z_1]}\bigg| Z_{i1} = z_1\bigg],
$$

\n
$$
\tilde{\mu}_s^0 = \lim_{z_1 \nearrow 0} E\bigg[\frac{Y_{i(2+s)}S_{i2}(D_{i2} - \lambda^0(X_i))}{(1 - \lambda^0(X_i))E[D_{i2}|Z_{i1} = z_1]}\bigg| Z_{i1} = z_1\bigg], \text{ and}
$$

\n
$$
\tilde{\mu}_s^1 = \lim_{z_1 \searrow 0} E\bigg[\frac{Y_{i(2+s)}S_{i2}(D_{i2} - \lambda^1(X_i))}{(1 - \lambda^1(X_i))E[D_{i2}|Z_{i1} = z_1]}\bigg| Z_{i1} = z_1\bigg],
$$

for all $s \geq 1$ *. In addition, treating first-stage decisions as outcomes,* $E[\eta_{i;1,1}|Z_1 = 0]$ *is identified by Lemma* [2.2](#page-10-0) *and* $E[\eta_{i;k,1}|Z_1=0]$ for all $k = 2, ..., \tau - 1$ is identified by (3.3) *recursively*.

The proof is given in the Supplemental Appendix. In Section A.4 of the Supplemental Appendix, we also discuss several important special cases of the dynamic RD model, including having an absorbing state treatment and not observing some initial rounds of RD data.

4. Estimation and inference

Estimation of the one-period-after ATE is discussed in Section [2.4](#page-11-0) for the benchmark two-period model. In the next, we first study inference of the proposed one-period-after ATE estimator. Then we extend the two-period estimation and inference strategy to the general multiperiod setting introduced in Section [3.](#page-12-0)

4.1 *Inference in the benchmark two-period setting*

The inference procedure proposed in this section for the one-period-after ATE estimator defined in Section [2.4](#page-11-0) adapts the weighted bootstrap procedure following [Ma and](#page-28-0) [Kosorok](#page-28-0) [\(2005\)](#page-28-0). The procedure is tractable in empirical applications as it keeps estimation and inference of different long-term ATEs within a uniform format. The procedure does not pursue bandwidth choice optimality in the sense of asymptotic mean squared errors (AMSE), however. In the Supplemental Appendix, we discuss an alternative AMSE-optimal estimation and inference procedure for the one-period-after ATE based on [Calonico, Cattaneo, and Titiunik](#page-25-0) [\(2014\)](#page-25-0), [Calonico, Cattaneo, and Farrell](#page-25-0) [\(2018,](#page-25-0) [2020,](#page-25-0) [2022\)](#page-25-0). 8 The weighted bootstrap procedure discussed in this section could also be adapted for recursive CFR estimators.

4.1.1 *Assumptions and asymptotic properties* Let $\phi_{\gamma^1, ni}(D_{2i}, S_{2i}, Z_{1i}, X_i)$ and $\phi_{\gamma^0,ni}(D_{2i}, S_{2i}, Z_{1i}, X_i)$ be influence functions of estimators $\hat{\gamma}^1$ and $\hat{\gamma}^0$ defined in Section [2.4,](#page-11-0) respectively, such that

$$
\sqrt{nh}(\hat{\gamma}^1 - \gamma^1) = \frac{1}{\sqrt{nh}} \sum_{i=1}^n \phi_{\gamma^1,ni}(D_{2i}, S_{2i}, Z_{1i}, X_i) + o_p(1),
$$

$$
\sqrt{nh}(\hat{\gamma}^0 - \gamma^0) = \frac{1}{\sqrt{nh}} \sum_{i=1}^n \phi_{\gamma^0,ni}(D_{2i}, S_{2i}, Z_{1i}, X_i) + o_p(1).
$$

Let $\phi_{\alpha^1,ni}(Y_{2i},D_{2i},S_{2i},Z_{1i},X_i)$ and $\phi_{\alpha^0,ni}(Y_{2i},D_{2i},S_{2i},Z_{1i},X_i)$ be influence functions of infeasible estimators $\tilde{\alpha}^1$ and $\tilde{\alpha}^0$ defined by the following:

$$
(\tilde{\alpha}^1, \tilde{\beta}^1) = \arg\min_{\alpha, \beta} \sum_{i=1}^n 1(Z_{1i} \ge 0) K\left(\frac{Z_{1i}}{h}\right) [A_i(\alpha, \beta; \gamma^1)]^2,
$$

$$
(\tilde{\alpha}^0, \tilde{\beta}^0) = \arg\min_{\alpha, \beta} \sum_{i=1}^n 1(Z_{1i} < 0) K\left(\frac{Z_{1i}}{h}\right) [A_i(\alpha, \beta; \gamma^0)]^2.
$$

The infeasible estimators are generated by the same local linear regressions as used in Section [2.4](#page-11-0) for estimators $\hat{\alpha}^1$ and $\hat{\alpha}^0$, but assuming known first-step propensity scores.

⁸Extending the robust inference procedure to longer-term ATE estimators could be realized through calculating first-order linear approximations of each τ-period-after estimator (e.g., Sections 4.1 and 4.2 of [Calonico, Cattaneo, and Titiunik](#page-25-0) [\(2014\)](#page-25-0)) for bias correction and optimal bandwidth choice calculation. It would be an interesting topic for future research.

Define gradient terms $\nabla^1_\gamma = \lim_{z_1 \searrow 0} E[\nabla_\gamma [\frac{Y_2 S_2(D_2 - p(X, \gamma))}{1 - p(X, \gamma)}]_{\gamma = \gamma^1} |Z_1 = z_1]$ and $\nabla^0_\gamma =$ $\lim_{z_1\nearrow 0} E[\nabla_\gamma \left[\frac{Y_2S_2(D_2-p(X,\gamma))}{1-p(X,\gamma)}]\big|_{\gamma=\gamma^0} |Z_1=z_1|$. By the delta method, we obtain the following influence function representation of $\hat{\alpha}^0$ and $\hat{\alpha}^1$ such that for $d_1 = 0, 1$, we have

$$
\sqrt{nh}(\hat{\alpha}^{d_1} - \alpha^{d_1})
$$
\n
$$
= \frac{1}{\sqrt{nh}} \sum_{i=1}^n (\tilde{\phi}_{\alpha^{d_1}, ni}(Y_{2i}, S_{2i}, D_{2i}, Z_{1i}, X_i) - \nabla_{\gamma}^{d_1} \cdot \phi_{\gamma^{d_1}, ni}(D_{2i}, S_{2i}, Z_{1i}, X_i)) + o_p(1)
$$
\n
$$
\equiv \frac{1}{\sqrt{nh}} \sum_{i=1}^n \phi_{\alpha^{d_1}, ni}(Y_{2i}, S_{2i}, D_{2i}, Z_{1i}, X_i) + o_p(1).
$$
\n(4.1)

The representation implies that the asymptotic variance of $\bar{\theta}_{1,1}$ could be estimated by

$$
\hat{V}_{11} = \frac{1}{nh} \sum_{i=1}^{n} (\hat{\phi}_{\alpha^1,ni}(Y_{2i}, D_{2i}, S_{2i}, Z_{1i}, X_i))^2 + (\hat{\phi}_{\alpha^0,ni}(Y_{2i}, D_{2i}, S_{2i}, Z_{1i}, X_i))^2,
$$

where $\phi_{\alpha^{d_1},ni}(Y_{2i},D_{2i},S_{2i},Z_{1i},X_i)$ is the estimated version of $\phi_{\alpha^{d_1},ni}(Y_{2i},D_{2i},S_{2i},Z_{1i},$ X_i) with all unknown parameters replaced with corresponding estimators; $d_1 = 0, 1$.

We next provide detailed assumptions and asymptotic properties of the proposed two-step estimator with respect to a varying coefficient logit first stage. For notational simplicity, we assume for the rest of the paper that the X_i vector includes a constant. Then a varying coefficient logit first-stage model is formulated as $p(x, \gamma) = L(x' \gamma)$ with $L(a) = \exp(a)/(1 + \exp(a)).$

Assumption 4.1. $\lambda(x; z_1) = L(x'\gamma(z_1))$ *is the correct specification on* $z_1 \in \mathcal{N}_{\epsilon}$ *for some* $\epsilon > 0$.

Assumption 4.2. *Density* $f_{z_1}(z_1)$ *is twice continuously differentiable in* z_1 *on* \mathcal{N}_{ϵ} *, and* $f_{z_1}(z_1)$ *is bounded away from zero on* \mathcal{N}_{ϵ} for some $\epsilon > 0$.

Assumption 4.3. *Assume that*:

- 1. *The kernel function* K(·) *is a nonnegative symmetric bounded kernel with support* $[-1, 1]; \int K(u) du = 1.$
- 2. *The bandwidth satisfies that* $h \to 0$, $nh^3 \to \infty$, and $nh^5 \to 0$ as $n \to \infty$.

Assumption 4.1 requires that the varying coefficient logit model is correctly specified. Assumption 4.2 imposes standard smoothness conditions on the density of the running variable. Assumption 4.3 imposes standard conditions on the kernel function and undersmoothed bandwidth. Undersmoothing is required such that the bias of kernel estimators becomes asymptotically negligible. In practice, we recommend using the triangular kernel (i.e., $K(x) = |x| \cdot 1(|x| < 1)$) and undersmoothing the robust RD bandwidth introduced in [Calonico, Cattaneo, and Titiunik](#page-25-0) [\(2014\)](#page-25-0) (CCT), which is of order $n^{1/5}$. As discussed earlier, undersmoothing is not AMSE optimal. In the Supplemental

Appendix, we propose an alternative procedure that uses bias correction and AMSEoptimal bandwidth in the second step. The alternative procedure also requires a higherorder local polynomial and a larger bandwidth in the first step such that estimation errors from the first step do not affect AMSE of the final estimator.

The following lemma provides asymptotic properties of the first-step varying coefficient logit estimators. Similar results could be derived if the propensity score function λ(.; .) follows other semiparametric models such as varying coefficient Probit.

LEMMA [4.1](#page-17-0). *Suppose that Assumptions* 4.1–[4.3](#page-17-0) *and* B.1–B.2 *hold. Then for* $d = 0, 1$ *, we have*

$$
\sqrt{nh} \left(\begin{matrix} \hat{\gamma}^d - \gamma^d \\ h \hat{\beta}_{\text{FS}}^d - h \beta^d \end{matrix} \right) = \frac{1}{\sqrt{nh}} \sum_{i=1}^n (\Delta^d)^{-1} S_{2i} \cdot 1(Z_{1i} \ge 0)^d \cdot 1(Z_{1i} < 0)^{1-d}
$$

$$
\cdot K(Z_{1i}/h) \left(D_{2i} - L(X_i'(\gamma^d + \beta^d Z_{1i})) \right) \left(\begin{matrix} X_i \\ Z_{1i} X_i / h \end{matrix} \right) + o_p(1),
$$

where Δ^d *is given in equation* (D.2) *in the Supplemental Appendix. In addition, for* $d =$ 0, 1, *we have*

$$
\sqrt{nh} \begin{pmatrix} \hat{\gamma}^d - \gamma^d \\ h\hat{\beta}^d_{\text{FS}} - h\beta^d \end{pmatrix} \Rightarrow N(0, (\Delta^d)^{-1} \Omega^d (\Delta^d)^{-1}),
$$

where Ω^d *is given in equation* (D.3) *in the Supplemental Appendix.*

Aside from assumptions stated earlier, the lemma also requires Assumptions B.1 and B.2 in the Supplemental Appendix. The former imposes smoothness conditions on the varying coefficient in neighborhoods right above and below the RD cutoff. The latter imposes moment conditions on the conditioning covariates.

For asymptotic properties of $\hat{\alpha}^0$ and $\hat{\alpha}^1$, we impose additional Assumptions B.1 and B.4, stated in the Supplemental Appendix. The former includes smoothness conditions for the infeasible estimators $\tilde{\alpha}^0$ and $\tilde{\alpha}^1$ using true values of first-step propensity score functions. The latter imposes conditions that control the impact of first-step estimation errors on the asymptotic properties of feasible two-step estimators $\hat{\alpha}^0$ and $\hat{\alpha}^1$. Given the assumptions, $\sqrt{nh}(\hat{\alpha}^{d_1} - \alpha^{d_1})$, for $d_1 = 0$, 1, has linear representation as in [\(4.1\)](#page-17-0) with

$$
\tilde{\phi}_{\alpha^{d_1},ni}(Y_{2i}, D_{2i}, S_{2i}, Z_{1i}, X_i)
$$
\n
$$
= (10) \cdot \Delta_z^{-1} \cdot 1(Z_{1i} \ge 0)^{d_1} \cdot 1(Z_{1i} < 0)^{1-d} \cdot K(Z_{1i}/h)
$$
\n
$$
\cdot \left(Y_{2i} - E[Y_{2i}|Z_{1i}] - \frac{Y_{2i}S_{2i}(D_{2i} - L(X_i'\gamma^{d_1}))}{1 - L(X_i'\gamma^{d_1})} + E\left[\frac{Y_{2i}S_{2i}(D_{2i} - L(X_i'\gamma^{d_1}))}{1 - L(X_i'\gamma^{d_1})}\Big|Z_{1i}\right]\right)
$$
\n
$$
\cdot \left(\frac{1}{Z_{1i}/h}\right),
$$

where $\Delta_z = f_{z_1}(0) \cdot \left(\begin{array}{c} \mu_{z,0} & \mu_{z,1} \\ \mu_{z,1} & \mu_{z,2} \end{array}\right)$ $\mu_{z,1}$ $\mu_{z,2}$), and $\mu_{z,j} = \int_{u \geq 0} u^j K(u) du$ for $j = 1, 2, \dots$. The influence function representation then implies the following asymptotic results.

THEOREM [4.1](#page-17-0). *Suppose that Assumptions* 4.1–[4.3](#page-17-0) *and* B.1–B.4 *hold. For* $d_1 = 0, 1$ *, we then have*

$$
\sqrt{nh}(\hat{\alpha}^{d_1} - \alpha^{d_1}) \stackrel{d}{\to} N(0, V_{\alpha^{d_1}}), \quad d_1 = 0, 1;
$$

$$
\sqrt{nh}(\hat{\bar{\theta}}_{1,1} - \bar{\theta}_{1,1}) \stackrel{d}{\to} N(0, V_{\alpha^1} + V_{\alpha^0}),
$$

where $V_{\alpha^0} = \lim_{n \to \infty} \lim_{z_1 \to 0} h^{-1} E[\phi_{\alpha^0, ni}^2(Y_{2i}, D_{2i}, S_{2i}, Z_{1i}, X_i) | Z_{1i} = z_1]$ and $V_{\alpha^1} =$ lim_{n→∞} lim_{z1}_{\1} $h^{-1}E[\phi_{\alpha^1,ni}^2(Y_{2i}, D_{2i}, S_{2i}, Z_{1i}, X_i)|Z_{1i} = z_1]$.

The exact expressions of V_{α^0} and V_{α^1} are tedious to calculate in general. In the next section, we adapt the weighted bootstrap procedure first introduced in [Ma and Kosorok](#page-28-0) [\(2005\)](#page-28-0) to simulate the limiting distribution of the proposed estimator. Studies adopting the procedure in other settings include [Chen and Pouzo](#page-25-0) [\(2009\)](#page-25-0), [Chernozhukov et](#page-25-0) [al.](#page-25-0) [\(2015\)](#page-25-0), [Chernozhukov, Fernández-Val, and Kowalski](#page-25-0) [\(2015\)](#page-25-0), and [Fernández-Val, van](#page-26-0) [Vuuren, and Vella](#page-26-0) [\(2021\)](#page-26-0), among many others. Our paper is the first to apply weighted bootstrap to kernel-based boundary estimation, which is the main workhorse of the RD literature.

4.1.2 *Weighted bootstrap inference* Let ${W_i}_{i=1}^n$ be a sequence of pseudo-random variables independent of the sample path with unit mean and variance. Define the weighted bootstrap estimator for $\bar{\theta}_{1,1}$ as

$$
\hat{\theta}_{1,1}^w = \hat{\alpha}^{1,w} - \hat{\alpha}^{0,w},
$$

\n
$$
(\hat{\alpha}^{1,w}, \hat{\beta}^{1,w}) = \arg\min_{\alpha,\beta} \sum_{i=1}^n W_i \cdot 1(Z_{1i} \ge 0) K\left(\frac{Z_{1i}}{h}\right) [A_i(\alpha, \beta; \hat{\gamma}^{1,w})]^2,
$$

\n
$$
(\hat{\alpha}^{0,w}, \hat{\beta}^{0,w}) = \arg\min_{\alpha,\beta} \sum_{i=1}^n W_i \cdot 1(Z_{1i} < 0) K\left(\frac{Z_{1i}}{h}\right) [A_i(\alpha, \beta; \hat{\gamma}^{0,w})]^2,
$$

where

$$
(\hat{\gamma}^{1,w}, \hat{\beta}_{FS}^{1,w}) = \arg \max_{\gamma, \beta} \sum_{i=1}^{n} W_i \cdot S_{2i} 1(Z_{1i} \ge 0) K\left(\frac{Z_{1i}}{h}\right)
$$

$$
\cdot [D_{2i} \log p(X_i, \gamma + \beta Z_{1i}) + (1 - D_{2i}) \cdot \log(1 - p(X_i, \gamma + \beta Z_{1i}))],
$$

$$
(\hat{\gamma}^{0,w}, \hat{\beta}_{FS}^{0,w}) = \arg \max_{\gamma, \beta} \sum_{i=1}^{n} W_i \cdot S_{2i} 1(Z_{1i} < 0) K\left(\frac{Z_{1i}}{h}\right)
$$

$$
\cdot [D_{2i} \log p(X_i, \gamma + \beta Z_{1i}) + (1 - D_{2i}) \cdot \log(1 - p(X_i, \gamma + \beta Z_{1i}))].
$$

The weighted bootstrap procedure is simple to carry out. Given a simulated copy of ${W_i}_{i=1}^n$, weighted bootstrap repeats the original two-step kernel-based estimation procedure (i.e., first-step local MLE propensity score estimation and second-stage local linear regressions), replacing the original kernel weights $K(Z_{1i}/h)$ with new weights

 $W_i \cdot K(Z_{1i}/h)$. The procedure could also be easily extended to adjust for within-cluster correlations by assigning random W_i at the cluster level.

Following [Ma and Kosorok](#page-28-0) [\(2005\)](#page-28-0), $\sqrt{n}h(\hat{\theta}_{1,1}^w - \hat{\theta}_{1,1})$ and $\sqrt{n}h(\hat{\theta}_{1,1} - \bar{\theta}_{1,1})$ have the same limiting distribution under suitable conditions. The next theorem formalizes the validity of the weighted bootstrap estimator given a varying coefficient logit first stage.

THEOREM 4.2. *Suppose that Assumptions* [4.1](#page-17-0)–[4.3](#page-17-0) *and B.1–B.4 hold and that* $\{W_i\}_{i=1}^n$ *is a sequence of i.i.d. pseudo-random variables independent of the sample path with* $E[W_i] =$ $Var[W_i] = 1$ *for all i. We then have*

$$
\sqrt{nh}\left(\hat{\bar{\theta}}_{1,1}^w - \hat{\bar{\theta}}_{1,1}\right) \stackrel{d}{\rightarrow} N(0, V_{\alpha^1} + V_{\alpha^0})
$$

conditional on the sample path with probability approaching one.

Although W_i can follow any distribution with unit mean and variance, in the simulation and empirical sessions where the first-step propensity score function is modeled with varying-coefficient logit, we use a discrete distribution where $W_i = 0.5$ or 3 with probabilities 0.8 and 0.2, respectively. The binary random variable with positive support ensures that the weighted logit objective functions remain globally concave.

4.2 *Estimation and inference in the general multiperiod setting*

Long-term ATEs in the multiperiod setting or $E[\theta_{i;\tau,1}|Z_{i1} = 0]$ for $\tau \geq 2$ are identified in Lemma [3.2.](#page-15-0) This section elaborates their estimation and inference.

Let us start with case of $\tau = 2$. To estimate the two-period-after ATE, or $\bar{\theta}_{2,1} \equiv$ $E[\theta_{i;2,1}|Z_{i1} = 0]$, one can first estimate the one-period-after average first-stage effect $\bar{\eta}_{1,1} \equiv E[\eta_{i;1,1}|Z_{i1} = 0]$ following the estimation procedure for one-period-after ATE, or $\bar{\theta}_{1,1}$, described in Section [2.4,](#page-11-0) treating first-stage treatment decisions as outcomes. Then one can estimate other components of equation [\(3.3\)](#page-15-0). Similarly, the estimation of any τ -period-after ATE for $\tau \geq 3$ involves estimating the average first-stage effect $\bar{\eta}_{k,1} \equiv E[\eta_{i;k,1}|Z_{i1} = 0]$ for all $k = 1, 2, ..., \tau-1$, which can be done recursively following Lemma [3.2,](#page-15-0) and separate estimation of other components in equation [\(3.3\)](#page-15-0).

We formally define the estimator of $\bar{\theta}_{2,1}$. Rewriting Lemma [3.2](#page-15-0) with $\tau = 2$ gives

$$
\bar{\theta}_{2,1} = \alpha_1^1 - \alpha_1^0 - \left(\tilde{\mu}_{nu}^0 / \tilde{\mu}_{de}\right) \bar{\eta}_{1,1}, \quad \text{where } \tilde{\mu}_{nu}^0 = \lim_{z_1 \nearrow 0} E\left[\frac{Y_{i2} S_{i2} (D_{i2} - \lambda^0(X_i))}{1 - \lambda^0(X_i)} | Z_{i1} = z_1 \right],
$$

$$
\tilde{\mu}_{de} = E[D_{i2} | Z_{i1} = z_1],
$$

$$
\alpha_1^1 = \lim_{z_1 \searrow 0} E\bigg[Y_{i3} - \frac{Y_{i3}S_{i2}(D_{i2} - \lambda^1(X_i))}{1 - \lambda^1(X_i)} | Z_{i1} = z_1 \bigg],
$$

$$
\alpha_1^0 = \lim_{z_1 \nearrow 0} E\bigg[Y_{i3} - \frac{Y_{i3}S_{i2}(D_{i2} - \lambda^0(X_i))}{1 - \lambda^0(X_i)} | Z_{i1} = z_1 \bigg].
$$

Let $\hat{\alpha}_1^1$, $\hat{\alpha}_1^0$, $\hat{\tilde{\mu}}_{de}$, $\hat{\alpha}_{ds}^1$, and $\hat{\alpha}_{fs}^0$ be estimators of α_1^1 , α_1^0 , $\tilde{\mu}_{au}^0$, $\tilde{\mu}_{de}$, α_{fs}^1 , and α_{fs}^0 , respectively. All of them can be defined using the same two-step semiparametric pro-cedure described in Section [2.4](#page-11-0) for the estimation of $\hat{\alpha}^0$ and $\hat{\alpha}^1$, where the first-step propensity estimation uses kernel-based local MLE. Let $\phi_{\alpha_1^1, ni}$, $\phi_{\alpha_1^0, ni}$, $\phi_{\tilde{\mu}_{au}^0, ni}$, $\phi_{\tilde{\mu}_{de}^0, ni}$, $\phi_{\alpha_{fs}^1,ni}$, and $\phi_{\alpha_{fs}^0,ni}$ denote the influence functions of the estimators, respectively. Definitions of $\phi_{\alpha_1^1,ni},\,\phi_{\alpha_1^0,ni},\,\phi_{\tilde\mu_{nu}^0,ni},\,\phi_{\alpha_{fs}^1,ni},$ and $\phi_{\alpha_{fs}^0,ni}$ are similar to influence functions given in equation [\(4.1\)](#page-17-0) for $\hat{\alpha}^0$ and $\hat{\alpha}^1$. The influence function for $\hat{\mu}_{de}$ is defined as $\phi_{\tilde{\mu}_{de},ni} = \frac{1}{f_{z_1}(0)} K(\frac{Z_{1i}}{h})(D_{2i} - E[D_{2i}|Z_{1i}]).$

Let $\bar{\theta}_{2,1}=\hat{\alpha}_1^1-\hat{\alpha}_1^0-\hat{\tilde{\mu}}_{nu}^0/\hat{\tilde{\mu}}_{de}(\hat{\alpha}_{fs}^1-\hat{\alpha}_{fs}^0)$ be the estimator of $\bar{\theta}_{2,1}$. By the delta method, we have $\sqrt{nh}(\hat{\theta}_{2,1} - \bar{\theta}_{2,1}) = \frac{1}{\sqrt{n}}$ $\frac{1}{n\hbar}\sum_{i=1}^{n}\phi_{\bar{\theta}_{2,1},ni}(Y_{3i},Y_{2i},D_{3i},D_{2i},S_{2i},Z_{1i},X_i) +$

 $o_p(1)$, where $\phi_{\bar{\theta}_{2,1},ni}(Y_{3i}, Y_{2i}, D_{3i}, D_{2i}, S_{2i}, Z_{1i}, X_i) = \phi_{\alpha_1^1,ni} - \phi_{\alpha_1^0,ni} - \frac{\alpha_{fs}^1 - \alpha_{fs}^0}{\tilde{\mu}_{de}} \phi_{\tilde{\mu}_{nu}^0,ni} +$ $\frac{\tilde{\mu}^0_{nu}(\alpha^1_{fs}-\alpha^0_{fs})}{(\tilde{\mu}_{de})^2}\phi_{\tilde{\mu}_{de},ni}-\frac{\tilde{\mu}^0_{nu}}{\tilde{\mu}_{de}}(\phi_{\alpha^1_{fs},ni}-\phi_{\alpha^0_{fs},ni}).$ The asymptotic normality of $\hat{\bar{\theta}}_{2,1}$ follows from the influence function representation. Given the influence function representation, it is easy to see that the weighted bootstrap procedure could be applied here, too, and in general, to the inference problem of any τ -period-after ATE with $\tau \geq 2$.

Monte Carlo simulations for the proposed estimation and inference procedure are summarized in the Supplemental Appendix.

5. Empirical example: The effect of CA school bonds

This section revisits the study of local education bonds using the data set published by CFR. As described in CFR, school districts in California became eligible for issuing general obligation bonds through Proposition 46 in 1984. CFR study the effects of bond authorization on local house prices, student achievements, and other outcomes using California data from 1987 to 2006. Due to data limitations, we study two outcome variables: total expenditure per pupil and capital loading per pupil in a school district.

There are 1551 bond measures from 655 school districts with nonmissing vote share information. Although the data set starts from the first years of education bonds, the expenditure outcomes we use are not observed until 1995. Among all the bond measures, 282 are proposed after 5 or more years of inaction (no measure) and have nonmissing expenditure outcome data up to 4 periods after the measure year. We focus on long-term effects of these bond measures.

Figure [1](#page-22-0) gives a visual illustration of the data. The bottom row of the figure shows immediate and long-term total first-stage effects of passing an education bond measure. No school districts that barely passed the vote share cutoff in the first trial authorized another bond the following year. The probabilities increase slightly in years 3 and 4. Around 27% of school districts that barely missed the vote share cutoff in the first trial successfully authorized their first education bond in the following year. The negative first-stage effects imply that long-term average total effects observed directly from outcome discontinuity are smaller than the long-term ATEs of policy interests.

Table [1](#page-23-0) reports nonparametric estimation results of immediate and long-term average direct effects following the extended recursive CFR strategy formalized in Lemmas [2.1](#page-7-0) and A.1. The estimated average effects for the capital outlays outcome are highly statistically significant. Effects of the total expenditures outcome are only marginally

Figure 1. Average total effects and histograms. Note: The data set is from [Cellini, Ferreira, and](#page-25-0) [Rothstein](#page-25-0) [\(2010\)](#page-25-0). The kernel bandwidth of each row is set to the same value, which is the average of CCT bandwidths among all four RD regressions of the row. The data sample of the first two rows is a subset of that of the last row, because of missing values in the expense outcomes.

significant. Estimates in Table [1](#page-23-0) are larger than those reported in Table 4 of CFR. The difference comes from two sources. First, Table 4 of CFR is estimated by pooling different rounds of RDs. Under treatment effect heterogeneity, such a pooling strategy is not ap-

Note: The data set is from [Cellini, Ferreira, and Rothstein](#page-25-0) [\(2010\)](#page-25-0). Standard errors are calculated using weighted bootstrap with 1000 bootstrap repetitions. Undersmoothed CCT bandwidth is calculated following suggestions in Section E of the Supplemental Appendix, with the CCT bandwidth reported in Figure [1.](#page-22-0)

propriate, because marginal individuals at different rounds of RD cutoffs have different treatment effects. Second, Table 4 of CFR is estimated parametrically with global polynomials while Table 1 is estimated nonparametrically using the local linear method.

Table 2 reports estimation results following the proposed method. Varyingcoefficient logit is used in first-step propensity score estimation. Panel A of the table reports estimation and inference results when the CIA condition in Section [2](#page-3-0) holds without any conditioning covariate. Panel B of the table reports results when the first-period outcome is used as the first-stage conditioning covariate. The estimates are semiparametric and rely on the first-step varying-coefficient logit functional form of propensity

Immediate		One-period-after		Two-period-after		Three-period-after	
$k = 4.25$	4.5	$k = 4.25$	4.5	4.25	4.5	4.25	4.5
Panel A:							
	Total expenditures per pupil						
897	767	1070	959	1440	1266	2532	2331
(664)	(601)	(776)	(716)	(1453)	(1244)	(2874)	(1992)
	Capital outlays per pupil						
361	275	405	398	1245	1240	2850	2884
(248)	(216)	(158)	(149)	(448)	(401)	(882)	(760)
Panel B:							
	Total expenditures per pupil						
897	767	903	808	1016	863	1682	1511
(664)	(601)	(964)	(882)	(2073)	(1863)	(4684)	(3629)
	Capital outlays per pupil						
361	275	433	416	1387	1364	3176	3195
(248)	(216)	(176)	(164)	(495)	(472)	(1156)	(1146)

Table 2. Average direct effects: the proposed procedure.

Note: The data set is from [Cellini, Ferreira, and Rothstein](#page-25-0) [\(2010\)](#page-25-0). Standard errors are calculated using weighted bootstrap with 1000 bootstrap repetitions. Undersmoothed CCT bandwidth is calculated following suggestions in Section E of the Supplemental Appendix, with the CCT bandwidth reported in Figure [1.](#page-22-0) Panel A reports estimation results with nonparametric first-step propensity score estimators with no conditioning covariates. Panel B uses the first-period outcome as the conditioning covariate in the first-step propensity score estimation.

scores. Estimates of the two panels share the same patterns. Compared to the results of Table [1,](#page-23-0) long-term ATE estimates for the total expenditure outcome become smaller, although the estimation is not very precise. Long-term ATE estimates for the capital outlays outcome, on the other hand, are larger than those reported in Table [1](#page-23-0) and remain highly statistically significant.

6. Conclusion

Static RD models with a single eligibility test have been very popular in the last two decades. Recently, more empirical studies have targeted situations where individuals are eligible for repeated RD treatments. Most studies under such a setting have either ignored dynamics in repeated RD models or employed restrictive identifying assumptions. This paper is the first to employ the conventional potential outcome framework to identify long-term average direct treatment effects. Our proposed identification strategy allow explicitly for treatment effect heterogeneity under a conditional independence assumption and does not impose any assumption on endogenous RD participation decisions of later rounds. For estimation and inference, we propose a novel multistep semiparametric estimation procedure. Employing the proposed method, we revisit the study of local education bonds following CFR. We find much larger long-term average direct effects of education bonds on the capital outlays per pupil outcome.
